Abstract

An unusual thermal-magnetic hysteresis was observed between a minor magnetic transition around 120 K and the main one at 80 K in superconducting $\text{RuSr}_2(\text{R,Ce})_2\text{Cu}_2\text{O}_{10-\delta}$ (Ru1222R) samples, where R = Gd or Eu, down to a submicron length-scale. The observation suggests a possible phase-separation and is consistent with the very small but universal demagnetizing factor observed, which is difficult to reconcile with the canted spin-structure previously proposed. In such a scenario, the unusual superconducting properties of the Ru-based cuprates can also be understood naturally.

75.60.-d, 75.70.Cn, 74.72.Jt

The neutron-powder-diffraction (NPD) observation that the Ru-spins in $\text{RuSr}_2\text{GdCu}_2\text{O}_8$ (Ru1212), which is superconducting below 20–40 K, are antiferromagnetically (AFM) aligned below a magnetic transition-temperature $T_M \approx 133$ K makes its physics more complicated.^{1,2} Although canted Ru-spins have been proposed,^{1,4} the interpretation seems to be debatable. On one hand, the macroscopic moment of ceramic Ru1212 samples appears as that of a ferromagnet with a remnant moment of $m_r \approx 0.14 \mu_B/\text{cell}$.^{3,4} On the other hand, the NPD sets an upper limit of only $0.1 \mu_B/\text{cell}$ for the ferromagnetically (FM) aligned spins, M .^{1,4} Since M should be larger than $2m_r$ in a ceramic,⁵ the two measurements are difficult to reconcile with each other as canted spins. A possible way to accommodate these conflicting values is the existence of mesoscopic phase-separations. Previously, such a possibility has been disregarded based on a μSR measurement.³ We would like to point out, however, that the volume-fraction $\approx 2m_r/m_o$ of the possible FM species may be well below the experimental uncertainty of 20% with the Ru moment $m_o > 3 \mu_B/\text{cell}$.^{3,6} A similar debate in manganites further demonstrates that it is difficult to rule out phase-separations with only a few measurements.⁷ A re-examination of the Ru-based cuprates, therefore, is warranted. It should be noted that the magnetic configuration of Ru1212 is directly related to its superconductivity (SC). While “ordinary” SC may coexist with canted AFM, a phase-separation will result in the appearance of Josephson-junction arrays as previously proposed.⁸ The severe granularity of Ru1212 could thus be understood,^{3,9,10} similar to the heterogeneous magnetic structure of ErRh_4B_4 .¹¹

As part of our effort, the thermal-magnetic hysteresis of superconducting $\text{RuSr}_2\text{R}_{2-x}\text{Ce}_x\text{Cu}_2\text{O}_{10-\delta}$ (Ru1222R) with $\text{R} = \text{Gd}$ or Eu and x between 0.6 and 0.7, whose magnetic structure is expected to be similar to that of Ru1212,^{10,12} is studied. Our data confirm that there are minor weak-ferromagnetic transitions at $T_{M2} \approx 120$ K and $T_{M3} \approx 140$ K above the main transition at $T_{M1} \approx 80$ K, as reported previously.¹⁰ A dipole-dipole AFM interaction is further detected between the T_{M1} and the T_{M2} FM-species with a universal strength down to a length scale far smaller than the grain size, *i.e.* these two FM-species should coexist in a single structural grain. Furthermore, the strength, measured as the effective demagnetizing factor of the dipole field, is too small to be accommodated with a homogeneously canted-spin structure. A spatial correlation between the two species is needed. The observation, therefore, suggests a possible phase-separation between the FM species and a possible AFM matrix. Such a scenario can naturally account for many unusual superconducting properties previously reported in Ru1212/Ru1222.

Ceramic Ru1222 samples were synthesized following the standard solid-state-reaction procedure. Raw oxide powders were first prepared by calcination at 400–900 °C under flowing O_2 . Mixed powder with a proper cation ratio was then pressed into pellets and sintered at 900 °C in air for 24 hr. The final annealing was done at 1090 °C for 60 hr after repeatedly sintering at 1000 °C and regrinding.¹³ Pulverized samples of Ru1222R with different particle sizes sorted by the descending speeds in acetone were prepared. The structure was determined by powder X-ray diffraction (XRD) using a Rigaku DMAX-IIIB diffractometer. There are no noticeable impurity lines in the X-ray diffraction pattern within a resolution of a few percent. The grain sizes of the ceramic samples, the particle sizes of the powders, and the composition were measured using a JEOL JSM 6400 scanning electron microscope (SEM) and a JEOL JXA 8600 electron microprobe with attached Wavelength Dispersive Spectrometers (WDS). The cation-composition is homogeneous within our experimental

resolution ($\approx 1\text{--}2\%$). The magnetizations were measured using a Quantum Design SQUID magnetometer.

The field-cooled magnetization, M_{FC} , at 5 Oe is shown in the inset to Fig. 1 for a Ru1222Gd powder sample with a particle size of $\approx 1\text{ }\mu\text{m}$ and diluted with a large amount of epoxy. The particle size was far smaller than the grain size ($\approx 2\text{--}20\text{ }\mu\text{m}$) of the initial ceramic sample, and the powder should be regarded as a collection of single grains with negligible inter-particle (grain) interactions. Two additional transitions at T_{M2} and T_{M3} can be seen above the main transition at T_{M1} .¹⁴ Below 35 K, the zero-field-cooled magnetization, M_{ZFC} , becomes negative (not shown) and M_{FC} shows a diamagnetic drop, indicative of a superconducting transition (inset, Fig. 1). All of these observations are in qualitative agreement with the data previously reported.¹⁰

To determine whether the different transitions are associated with different structural grains, we examined the thermal-magnetic hysteretic effects; the spin-alignment of the T_{M1} species in highly diluted powder should not depend on their history above T_{M1} if one grain contains only one type of species.⁵ A procedure was thus designed as **A** (field-cooled under a fixed field of 10 Oe from 200 K to a temperature T_S) - **B** (switching field from 10 Oe to a lower field of H_S at T_S) - **C** (field-cooled under H_S from T_S to 60 K) - **D** (raising the temperature under H_S to 200 K) - **E** (field-cooled under H_S from 200 K to 60 K) (Fig. 1). It should be noted that the H_S was exactly the same between steps **C** and **E** and was measured using a Hall sensor with a resolution of 0.005 Oe. Additional tests that were performed demonstrated that the SQUID magnetometer is suitable to measure ferromagnets down to 10^{-2} Oe if precautions are taken.¹⁵

The M_{FC} -jump across T_{M1} , $\Delta M_{FC}(H_S, T_S) \equiv M_{FC}|_{at\ 60\text{ K}} - M_{FC}|_{at\ 95\text{ K}}$, and the magnetization just above T_{M1} , $M_{FC}(H_S, T_S) \equiv M_{FC}|_{at\ 95\text{ K}}$, were used here to measure the spin alignments of the T_{M1} species and the T_{M2} species, respectively. Both use a unit of emu per cm^3 Ru1222, *i.e.* a “nominal” moment without considerations of the epoxy-filling. During the T_{M1} transition, the spins of a T_{M1} species should be ordered under both H_S and interaction with the neighboring T_{M2} species. For a dipole-dipole interaction, the interaction should be proportional to the magnetization of the T_{M2} species around T_{M1} . However, $M_{FC}|_{at\ 95\text{ K}}$, *i.e.* the nominal moment at a slightly higher temperature, was used as an approximation to avoid interferences from the T_{M1} species. A correlation between ΔM_{FC} and $M_{FC}(H_S, T_S)$ was indeed observed. The ΔM_{FC} in step **C**, for example, is systematically lower than that in step **E**. In particular, the jump ΔM_{FC} in step **C** can even be negative under a positive H_S up to 0.5–0.6 Oe. It should be noted that this memory effect at low fields is qualitatively different from the well-known coercive-hysteresis of ferromagnets.⁵ For example, the observed ΔM_{FC} at a fixed $H_S = 0.05$ Oe changes sign when T_S crosses $T_{M1} \approx 80$ K (triangles in inset, Fig. 1). While the positive ΔM_{FC} at $T_S < 70$ K represents a typical coercive-hysteresis of the FM T_{M1} domains, the $\Delta M_{FC} < 0$ observed between 80 and 130 K demonstrates an AFM interaction between the T_{M1} and the T_{M2} domains. This sign change across T_{M1} demonstrates that the T_{M1} and T_{M2} species involve different spins and interactions.¹⁴

This AFM interaction can be seen more clearly in the inset of Fig. 2. The data of step **E** fall into a straight line through the origin as expected, while the data of step **C** show a molecular field of -0.6 Oe. We interpret the interaction as a demagnetizing field with or without additional interface interaction.^{16,17} It is difficult, unfortunately, to distinguish

between these two cases, and we will first discuss a pure dipole-dipole interaction. In such a case, the demagnetizing field can be written as $-f \cdot 4\pi M_{FC}(T_S, H_S)$, where f is a constant. Indeed, good linear correlation between the ΔM_{FC} and $M_{FC}(T_S, H_S)$ was observed in all powder/ceramic samples examined, supporting the dipole-dipole model (Fig. 2). An almost universal $f = 0.36 \pm 0.1$ was obtained by fitting $\Delta M_{FC} \propto [H - f \cdot 4\pi M_{FC}(T_S, H_S)]$ for all cubic-shape ceramic samples and unaligned powder samples with different Ru1222/epoxy ratios. This universal f is a surprise since the demagnetizing factor $4\pi f$ is expected to be $4\pi f_o V_R / (V_R + V_E)$ in the “nominal” magnetization-unit used if the T_{M1} and the T_{M2} species form separated grains, where f_o , V_R , and V_E are the geometric demagnetizing factor and the relative volumes of Ru1222 and epoxy, respectively. A dilution-independent f demonstrates that the T_{M1} and T_{M2} species coexist as nanodomains in the same structural grain, an indication of possible phase-separations.

It should be noted that geometric corrections are needed to convert the f observed in randomly oriented powders to that (identified as g in the discussion below) in a single grain with H along its easy-axis. In Ru1212, an easy axis has been suggested along the (a, b) plane.^{1,6} The significant M - H hysteresis of both the T_{M1} and T_{M2} species in Ru1222 suggests that a similar situation may exist. Below the coercive field, the only relevant components of both H and M_{FC} would be those along the easy axis. In such a case, the intragrain- and intergrain-contributions to f will be weighted differently if a correlation exists between the easy axes of the T_{M1} and the T_{M2} species in the same grain. The f of a thin ceramic disk with a diameter-to-thickness ratio of 5 was measured to verify that. The f observed was 0.25 and 0.5 with H perpendicular and parallel to its axis, respectively. The values, however, still differ significantly from the geometric factor of $f_o = 0.125$ and 0.75 expected for a homogeneous disk, *i.e.* the contributions from all neighboring grains are heavily suppressed. The suppression factor estimated is 2.5 based on above data, which is in rough agreement with the calculated value of 3 assuming that the intragrain T_{M1} and the T_{M2} species share the same easy axis but those in adjacent grains are random. It should be noted that the result is also in agreement with the universal f observed. The observation, *i.e.* two types of magnetic species coexist and share a common easy axis in the same structural grain, will be another piece of evidence for the existence of a phase separation.

We estimated the g in a local coordinate system with its z -axis being the common easy axis. The effective field H^* , the M_{FC} -jump across T_{M1} , $\Delta M_{FC}^*(H_S, T_S)$, and the magnetization just above T_{M1} , $M_{FC}^*(H_S, T_S)$, will be $H \cos \theta_1$, $\Delta M_{FC}(H_S, T_S) / \cos \theta_1$, and $M_{FC}(H_S, T_S) / \cos \theta_1$, respectively, where θ_1 is the polar angle of H . For unaligned powders, therefore, $g = f/3 \approx 0.12 \pm 0.03$. To verify the conclusion that the g is rather small, a Ru1222Eu sample was partially magnetically aligned by heating a mixture of the powder and wax to 400 K under a 5 T field. The $M_{FC} |_{at 5 K}$ of the cubic sample at 10 Oe were 0.21 emu/g and 0.29 emu/g with $H \parallel$ and $\perp$ to its axis, respectively. The f observed, on the other hand, were 0.37 and 0.29. Assuming an angular distribution of $1 - a \cdot \cos^2 \theta$, a $g \approx 0.1$ was extrapolated for $a = 0$.

The demagnetizing field of a dipole-array at $\mathbf{r}$ is the summation of an average field $-4\pi h M$ and a nearest-neighbor term of B_{near} , where h is the demagnetizing factor,¹⁷ and $h \approx 1/3$ for a sphere. The $B_{near}(\mathbf{r})$ oscillates rapidly with $\mathbf{r}$, but would be zero after averaging if there is no geometric correlations between $\mathbf{r}$ and $\mathbf{r}_i$, where $\mathbf{r}_i$ is the position of the nearest dipoles.¹⁷ This can be easily understood since the average field of a dipole $\mathbf{m}$ at the origin

is $\int [3(\mathbf{m} \cdot \mathbf{r})\mathbf{r} - \mathbf{m} |\mathbf{r}|^2] d^3\mathbf{r}$, which can be factorized as $\propto \int_0^\pi (3 \cos^2 \theta - 1) \sin \theta d\theta = 0$, where θ is the polar angle of $\mathbf{r}$. This average, therefore, will be only from the dipoles near the sample boundary where the factorization fails. Their contribution, however, is exactly the $-4\pi hM$ of the effective surface poles.¹⁷ In our case, the h should be $\approx 1/3$ based on the more-or-less spherical grains observed under SEM. To confirm that, a sample was measured at different H directions. Strong anisotropy is expected if the grains are far from spherical. The g deduced, however, is isotropic within 10%. A significant and positive $B_{near} \approx (1/3 - g) \cdot 4\pi M = 0.21 \cdot 4\pi M$ at the positions of the FM T_{M1} species, therefore, is required. That, as discussed above, can be true only if the FM T_{M1} species occupy merely a small fraction of the samples, *i.e.* the nearest T_{M1} and T_{M2} species are aligned along their easy axis. A phase separation between FM nanodomains and an AFM matrix is suggested.

Additional interface interactions might also exist.¹⁶ However, the fact that the $g = 0.12$ observed is almost universal and far smaller than the geometric factor $1/3$ expected requires a sample-independent but delicate balance between the dipole field and the interface interaction. This is very unnatural unless both the T_{M1} and T_{M2} nanodomains are the products of phase-separations.

It might be possible that this phase separation has a chemical origin, *i.e.* due to the inhomogeneity in Ce doping. In our opinion, however, this is unlikely: the scenario is not supported by our microprobe data; and the memory effect is qualitatively the same in our samples with different x . To further probe the topic, the M_{FC} at 1 T (solid diamonds) and the differential $ac \chi(T)$ at 5 T (open circles), as well as the intercept M_o of the $M-H$ loops of a Ru1222Eu sample (Eu was used to reduce the paramagnetic background) were examined (Fig. 3 and its inset). It is interesting to note that these parameters, which may serve as a measure for the volume-fraction of the respective species, vary smoothly around T_{M1} (Fig. 3), where a significant anomaly is expected if the T_{M2} and T_{M3} species were due to doping inhomogeneity (as demonstrated by the M_{FC} of Ru1212 at 1–6 T)⁴. Instead, the ferromagnetic contribution M_o shows a single transition at 140 K $\approx T_{M3} \gg T_{M1}$ (Fig. 3), as reported before.¹⁸ The M_{FC} and the $ac \chi(T)$ show similar behavior. The minor T_{M2} FM species observed, therefore, is unlikely to be merely due to the doping inhomogeneity.¹⁹

To understand the nature of the T_{M2} nanodomains (no comparable phenomena observed in Ru1212), a Curie-Weiss (C-W) fit (solid line) was calculated from M_{FC} at 1 T and above 180 K. A Curie constant of $C = 1.03$ emuK/mole ($\approx 2.8 \mu_B/\text{Ru}$ with $\mu(\text{Ce}) = 2.54 \mu_B$ and $\mu(\text{Eu}) = 0 \mu_B$) and a C-W temperature T_{CW} of 84 K $\approx T_{M1}$ were obtained. The increase of the χ with cooling, however, significantly slows down below $1.5T_{M1}$, and is even lower than the C-W fit below $1.25T_{M1}$. These are in line with the observed $ac \chi(T)$ with a dc bias of 5 T, which peaks around 120 K $\gg T_{M1}$. All of these, however, are in great contrast with Ru1212Eu, whose $dc \chi(1 \text{ T})$ stays above the C-W and whose $ac \chi(T)$ increases with cooling down to its AFM transition temperature.^{6,15} A short-range AFM correlation, therefore, seems to exist far above T_{M1} in Ru1222, and may be closely related to the T_{M2} species observed. This is slightly different from Ru1212, but offers an opportunity to probe the magnetitic structures below T_{M1} .

It should be pointed out that a phase separation of Ru1222 into a FM species and an AFM species will offer a natural interpretation for many unusual superconductive properties of Ru1212/Ru1222,^{8,9} although a detailed structure study is needed to confirm our proposition.

In summary, several magnetic transitions and an unusual thermal-magnetic memory

effect between them were observed in Ru1222. Detailed analysis of the magnetization under different thermal-magnetic conditions led us to the suggestion of a phase separation of Ru1222 into FM and AFM nanodomains inside the crystal grains. Such a suggestion can also account for the unusual superconducting properties reported in the Ru-based cuprates. A direct detailed magnetic structure study is warranted to confirm our proposition.
